Japan's Voluntary Lockdown*

Tsutomu Watanabe[†]

August 26, 2020

Abstract

Japan's government has taken a number of measures, including declaring a state of emergency, to combat the spread COVID-19. We examine the mechanisms through which the government's policies have led to changes in people's behavior. Using smartphone location data, we construct a daily prefecture-level stay-at-home measure to identify the following two effects: (1) the effect that citizens refrained from going out in line with the government's request, and (2) the effect that government announcements reinforced awareness with regard to the seriousness of the pandemic and people voluntarily refrained from going out. Our main findings are as follows. First, the declaration of the state of emergency reduced the number of people leaving their homes by 8.6% through the first channel, which is of the same order of magnitude as the estimate by Goolsbee and Syverson (2020) for lockdowns in the United States. Second, a 1% increase in new infections in a prefecture reduces people's outings in that prefecture by 0.026%. Third, the government's requests are responsible for about one quarter of the decrease in outings in Tokyo, while the remaining three quarters are the result of citizens obtaining new information through government announcements and the daily release of the number of infections. Our results suggest that what is necessary to contain the spread of COVID-19 is not strong, legally binding measures but the provision of appropriate information that encourages people to change their behavior.

*We would like to thank Kosuke Aoki, Gita Gopinath, Michihiro Kandori, Takayuki Mizuno, Makoto Nirei, Takaaki Ohnishi, Katsumi Tanabe, and Takashi Ui for helpful discussions and comments. We also thank Takayuki Mizuno for providing us with the data for the stay-at-home measure, and to Ayaka Nakahara for research assistance. This research forms part of the project on "Central Bank Communication Design" funded by the JSPS Grant-in-Aid for Scientific Research No. 18H05217. Tomoyoshi Yabu gratefully acknowledges financial support from the JSPS through the Grant-in-Aid for Scientific Research No. 20K01594.

1 Introduction

In response to the spread of COVID-19, the Japanese government on February 27 issued a request to local governments such as prefectural governments to close schools. Subsequently, the Japanese government declared a state of emergency on April 7 for seven prefectures, including Tokyo, and on April 16 expanded the state of emergency to all 47 prefectures. Prime Minister Abe called on citizens to reduce social interaction by at least 70% and, if possible, by 80% by refraining from going out. In response to these government requests, people restrained from going out. For example, in March, the share of people in Tokyo leaving their homes was down by 18% compared to January before the spread of COVID-19, and by April 26, during the state of emergency, the share had dropped as much as 64%. As a result of people refraining from leaving their homes, the number of daily new infections in Tokyo fell from 209 at the peak to two on May 23, and the state of emergency was lifted on May 25.¹

Unlike the lockdowns in China, the United States, and European countries such as Italy, restrictions during Japan’s state of emergency had no legal binding force. There were no penalties such as fines or arrests for leaving the house during the state of emergency. The police did not warn anyone who was out on the streets. The situation in Japan was one of a “voluntary lockdown.”² Looking at the “Government Response Stringency Index” – a composite measure of nine response indicators published by the University of Oxford’s Blavatnik School of Government – shows that the value for Japan of 47.22 at the end of April during the state of emergency was considerably smaller than those for France (87.96), the United States (72.69), the United Kingdom (75.93), Germany (76.85), Italy (93.52), and Canada (72.69).³ Instead, the value for Japan was essentially on the same level as that for Sweden (46.30). Looking at individual indicators, the status for “Restrictions on public gatherings” was “No restrictions” and that for “Closures of public transport” was “No measures,” which is quite different

¹However, as economic activity resumed after the state of emergency had been lifted, the number of new infections in Tokyo began to increase again in late June, surpassing the peak before the state of emergency.

²Regarding the difference between Japan and other countries, Gordon (2020) observes: “Many commentators both within Japan and around the world have emphasized the uniqueness of Japan’s relatively soft “state of emergency,” which, even though enacted by law, relies on requests and instructions rather than orders, fines, or arrests.” Examples of overseas media reports highlighting that measures by the Japanese government were not legally binding include the following: “Japan’s halfhearted coronavirus measures are working anyway” (Foreign Policy, May 14, 2020; online: <https://foreignpolicy.com/2020/05/14/japan-coronavirus-pandemic-lockdown-testing>); “Did Japan just beat the virus without lockdowns or mass testing?” (Bloomberg, May 22, 2020; online: <https://www.bloomberg.com/news/articles/2020-05-22/did-japan-just-beat-the-virus-without-lockdowns-or-mass-testing>); and “From near disaster to success story: How Japan has tackled coronavirus” (The Guardian, May 22, 2020; online: <https://www.theguardian.com/world/2020/may/22/from-near-disaster-to-success-story-how-japan-has-tackled-coronavirus>).

³<https://www.bsg.ox.ac.uk/research/research-projects/coronavirus-government-response-tracker>

from other countries. Similarly, with regard to “Stay-at-home requirements,” restrictions in Japan were weaker than in other countries: while in Japan people were “recommended” to stay at home, in the United States and various European countries they were “Required not to leave the house with exceptions.”

The fact that the behavior of people in Japan changed even though the country only took measures that were not legally binding suggests that the (legally binding) lockdowns in other countries were not the only reason people changed their behavior. The aim of this study is to clarify the mechanisms by which the non-legally binding policies of the Japanese government led people to change their behavior such as refraining from going out.⁴

In this study, we focus on the following two channels through which the Japanese government’s measures to prevent the spread of COVID-19 changed people’s behavior. The first channel is the “intervention effect.” This refers to changes in people’s behavior as a result of obeying government orders and requests to refrain from leaving their homes. In the case of first Wuhan in China and then the United States and Europe, this took the form of severe lockdowns, in which the government used legal powers to deprive people of their freedom of movement. In Japan’s case, the state of emergency was not legally binding and, if anything, was very limited, so that it is appropriate to regard it as a “request” from the government. On the other hand, the closure of schools by the Japanese government had a compulsory aspect.

The second channel is the “information effect.” Generally, when a government implements a policy on something, it can be assumed that it makes its decisions based on various types of information gathered before reaching the decision. Therefore, government decisions provide the public with information about the current situation. This is the signaling effect of government measures. Applying this to measures such as the state of emergency declaration, it can be thought that the public obtained new information on the status of infections through the government’s announcements. In developed countries, including Japan, details on infections are generally not disclosed to the public to protect the privacy of those infected. This means that governments have considerably more information than

⁴Although unrelated to the topic of this study, why Japan did not implement legally binding measures is also an important question. As highlighted by Kushner (2020), in the past, Japan used to give the police legal authority to enforce testing and quarantining in order to prevent the spread of cholera and leprosy. A very strict isolation policy was adopted, especially for leprosy patients. As pointed out by Kushner, however, both at the time and today these severe measures have been strongly criticized, and for this reason the Japanese government was unable to declare a state of emergency with legally enforceable restrictions on individual liberties, which would have been perceived as heavy-handed.

is in the public domain (or at least this is what many people believe), so that government actions have a strong signaling effect.

To examine the role that these two channels played in affecting people’s behavior, we use smart-phone location data to construct a daily prefecture-level measure showing the degree to which people stayed at home (calculated as the percentage decline relative to January 2020, i.e., before the pandemic, in the number of people leaving their homes multiplied by the time outside the home). We then construct panel data to examine the effect of the two major government measures to contain infections – the declaration of the state of emergency and the closure of schools – on the stay-at-home measure. Importantly, in doing so, we distinguish between the intervention effect and the information effect. We do so by utilizing the fact that the timing of the start and the end of the state of emergency and of school closures differed across prefectures. For example, in Tokyo, a state of emergency was declared on April 7, but at that time no state of emergency had been declared in Tochigi prefecture, which is located 100km north of Tokyo, about an hour on the bullet train. In Tochigi prefecture, a state of emergency was declared on April 16. Therefore, there was no intervention effect in Tochigi prefecture from April 7 to 15. However, people in Tochigi prefecture were aware that a state of emergency had been declared in Tokyo, so there was an information effect, and the number of people leaving their homes decreased. On the other hand, people in Tokyo refrained from leaving their homes due to both factors, i.e., the intervention effect and the information effect. Therefore, assuming that people in Tokyo and Tochigi had the same information about infections and there was no difference in the information effect between the two prefectures, it is possible to extract the intervention effect by observing the difference in the stay-at-home measure of the two prefectures. As for the state of emergency, not only did the timing when it started differ across prefectures, but the lifting also was divided into three waves, so that the intervention effect can be identified by utilizing the difference in timing. Similarly, with regard to school closures, the date when school closures were lifted varies widely across prefectures, which can be used to identify the intervention effect.

The main findings of this study are as follows. First, the state of emergency had the effect of reducing outings by 20 percentage points compared to before the pandemic. Of these 20 percentage points, 7 percentage points were due to the intervention effect, while the remainder was due to the information effect. The estimated intervention effect is of the same order of magnitude as the estimate by Goolsbee and Syverson (2020) for lockdowns in the United States. On the other hand,

school closures had the effect of reducing outings by 12 percentage points compared to before the pandemic. Of these 12 percentage points, 5 percentage points were due to the intervention effect. Second, an increase in the number of new infections within a particular prefecture had the effect that people in that prefecture reduced their outings: a 1% increase in the number of new infections in a prefecture reduced outings in that prefecture by 0.026%. People also reduced outings in response to the nationwide total of new infections. Third, if we decompose the reduction in outings in Tokyo into the intervention effect and the information effect, the contribution of the intervention effect is about one quarter, while the contribution of the information effect is three quarters, indicating that the dominant channel for changes in behavior was the information effect. Our findings show that people in Japan voluntarily reduced their outings based on various kinds information such as announcements of measures by the government and daily announcements of the number of infections. The results thus suggest that what is necessary for containing infections is not strong legally binding measures but the provision of appropriate information to encourage people to change their behavior.

There already is a considerable body of research on the economic impact of COVID-19, and the number of studies is increasing rapidly. Against this background, the present study is most closely related to the following three areas of research. The first is research on changes in behavior and the reduction in outings using smartphone location data. Examples of studies in this area include Alexander and Karger (2020), Barrios and Hochberg (2020), Couture et al. (2020), Chiou and Tucker (2020), and Gupta et al. (2020).

The second related area is studies on the impact of lockdown policies in the United States on people's movement and behavior. Examples include the studies by Forsythe et al. (2020), Rojas et al. (2020), Coibion et al. (2020), Goolsbee and Syverson (2020), Alexander and Karger (2020), and Gupta et al. (2020). The main interest of the present study is why the Japanese government's countermeasures against COVID-19 brought about changes in behavior even though they were not legally binding, and what is interesting in this regard is that a number of studies using U.S. data highlight that the lockdowns imposed by governments account for only a limited part of changes in people's behavior in the United States. For example, Goolsbee and Syverson (2020), using the fact that lockdowns were not implemented simultaneously across the entire United States but that the timing differed by state and county, compare counties that at a particular time were under lockdown and those that were not to examine whether there were significant differences in consumers' shopping behavior. They find that

although differences between counties under lockdown and not under lockdown certainly existed, they were not that large. Meanwhile, Rojas et al. (2020) focus on the fact that the timing of school closures differed across states and examine whether there were differences in new claims for unemployment insurance between states that at a particular time were under lockdown and those that were not. They find that there were no statistically significant differences. That changes in American’s behavior may not be due to (legally binding) lockdowns was also pointed out by Chetty et al. (2020). These studies highlight that changes in behavior in the United States were not the result of legally binding measures taken by the government but the result of U.S. citizens’ voluntary response to infections.⁵

The third area to which our study is related is research on the effects of lockdown policies in Asia. Focusing on China and using mobile phone location data, Fang et al. (2020) use difference-in-differences estimation to examine how the movement of people changed following the lockdown in Wuhan. They found that, controlling for other factors, the effect of the lockdown itself was to reduce the inflow of people into Wuhan by 76%, the outflow by 56%, and the movement of people within Wuhan by 54%. Meanwhile, focusing on South Korea, Aum et al. (2020) compared the Daegu-Gyeongbuk area, where infections were especially prevalent, with other areas in South Korea using difference-in-differences estimation. They found that an increase in the number of infected persons per 1,000 population by one was associated with a reduction in employment by 2–3%. In a study on Japan, Cato et al. (2020) examined how households’ expectations regarding the economic outlook differed immediately before and after the Governor of Tokyo held a press briefing on March 25 to explain the severity of infections. They show that, after hearing the press briefing, people’s concerns about employment, prices, shortages of medical supplies and daily necessities, etc., increased.

The remainder of this study is organized as follows. Section 2 provides an overview of COVID infections in Japan. Sections 3 and 4 respectively describe the methods and data used in the empirical analysis. Next, Section 5 outlines the results of the empirical analysis. Finally, Section 6 presents the conclusion and discusses the policy implications of this study.

⁵A study using data for a country other than the United States is that by Sheridan et al. (2020), who compare Denmark, where the government used legal interventions on outings and economic activities to halt the spread of infections, and Sweden, where the government did not make such interventions. They find that the decline in economic activity, as observed in bank transaction data, was not significantly different and argue therefore government interventions were not a major cause of the economic contraction. Chudik et al. (2020) extend the standard susceptible-infected-recovered (SIR) model to incorporate compulsory and voluntary social distancing. Their simulation results show that compulsory social distancing is effective in flattening the epidemic curve, especially when it is targeted towards individuals most likely to spread the infection, while voluntary social distancing is relatively ineffective.

2 Outbreak of COVID-19 and Policy Responses in Japan

The first reported case of a COVID-19 infection in Japan – of a man who had traveled to Wuhan, China – was on January 16, 2020. Then, on February 5, 10 passengers of a cruise ship docked at Yokohama Port were confirmed to have caught the virus. The first death in Japan was reported on 10 February. Infections in Japan began to rise in earnest from the second half of February, and as of February 29, the cumulative number of infections had reached 242. Infections further accelerated in early March, so that by the end of the month the cumulative number of infections had reached 2,234. In response to the spread of infections, the government on February 27 requested elementary, junior high, and high schools nationwide to temporarily close, and on March 24 decided to postpone the Tokyo Olympic Games scheduled for the summer of 2020. Furthermore, on April 7, a state of emergency was declared for seven prefectures including Tokyo, and on April 16, this was expanded to all prefectures.

Figure 1 shows the number of daily new infections in Tokyo, represented by the orange bars. The number of new infections increased rapidly in late March, exceeding 100 on March 17 and exceeding 200 on April 10. With the declaration of the state of emergency, the number of new infections decreased and fell to almost zero in mid-May. However, the number of new infections started to increase again in the second half of May.

The blue line in Figure 1 is the stay-at-home measure created using mobile phone location data (details of how the measure is constructed are provided below). The line shows the extent to which Tokyo residents refrained from leaving their home compared to January 2020, before the pandemic. The figure indicates that as the number of new infections increased, people increasingly stayed at home. This shows that people updated their information on infections based on the number of new infections announced daily by the Tokyo governor and changed their behavior to avoid infection. Moreover, the stay-at-home measure jumped following the request for the temporary closure of schools on February 27 and the declaration of the state of emergency on April 7, showing that the government’s measures changed people’s behavior. Interestingly, the stay-at-home measure also increased on April 16, when the state of emergency was expanded to all prefectures. The state of emergency for Tokyo had already been declared on April 7, and the measure on April 16 should not have directly affected the residents of Tokyo. However, it is possible that although the measures targeted other prefectures, Tokyo residents

obtained new information on the spread of infections from the government’s announcement of the measure. Another point to note is that the stay-at-home measure remained at a high level of over 20% and thus higher than in January despite the fact that the state of emergency was lifted from late May to early June and schools were reopened. If the government’s request to refrain from leaving home was the main reason for the change in people’s behavior, the stay-at-home measure should have dropped to its original level as the request was lifted. That has not been the case, suggesting that a significant part of the change in people’s behavior is voluntary.

While Tokyo is the prefecture with the highest number of infections in Japan, some prefectures have had zero or very few infections. Figure 2 shows an example of a prefecture with a small number of infections. Specifically, it shows Ibaraki prefecture, which is located northeast of Tokyo. By the end of June, the total number of infections in Ibaraki prefecture was 179, which is only 3% of the number for Tokyo. The stay-at-home measure for Ibaraki prefecture has shown a rise since the beginning of March, although not to the same extent as that for Tokyo. The stay-at-home measure jumped immediately after the request for schools to close on February 27 and the declaration of the state of emergency on April 16. This indicates that the government’s request to refrain from leaving home had a certain effect even in areas with few infections such as Ibaraki prefecture. In addition, the stay-at-home measure for Ibaraki prefecture also shows a jump on April 7, when the state of emergency was declared for seven prefectures including Tokyo, but not Ibaraki itself. This suggests that residents of Ibaraki prefecture have been paying close attention to the situation in areas with high infections and have changed their behavior based on this.

3 Methodology

We construct and examine the stay-at-home measure for each of the 47 prefectures of Japan for the period from January 6 to June 28, 2020. Using this panel data, we identify the following.

First, we identify the “intervention effect” and the “information effect.” Government policies such as the declaration of the state of emergency and school closures occurred at different times across prefectures, and by using these differences in timing, it is possible to determine which of the two effects was responsible for changes in people’s behavior. For example, a state of emergency was declared in Tokyo on April 7, but at that time no state of emergency was declared for Tochigi prefecture, which is located 100km north of Tokyo, about an hour away on the bullet train. A state of emergency was

declared in Tochigi on April 16. Therefore, there was no intervention effect in Tochigi prefecture from April 7 to 15. However, people in Tochigi prefecture were aware that the state of emergency had been declared in Tokyo, so there was an information effect, and the stay-at-home measure rose accordingly. On the other hand, people in Tokyo refrained from leaving home due to both the intervention and information effects, and the stay-at-home measure rose. Therefore, assuming that people in Tokyo and Tochigi had the same information about infections and there was no difference in the information effect between the two prefectures, the intervention effect can be extracted by observing the difference in the stay-at-home measure between the two prefectures. As for the declaration of the state of emergency, not only did the time when it was declared differ across prefectures, but the lifting also occurred in three waves, so that differences in the timing of the lifting of the state of emergency can also be used to identify the intervention effect. Similarly, with regard to school closures, the timing of when school closures were lifted varies widely across prefectures, and this can also be used to identify the intervention effect. Meanwhile, since all measures against COVID-19 are carried out at the prefectural level, there are few differences across smaller administrative units within the same prefecture such as municipalities.

The second identification we carry out is to examine whether changes in people’s behavior depend on infections in their surroundings or in Japan as a whole. As seen in Figure 2, even in prefectures with a small number of new infections, people refrained from leaving home. This suggests that people may be making decisions about refraining from leaving home in response to the number of infections nationwide, not the number of infections in the prefecture. Since infections are concentrated in metropolitan areas such as Tokyo, the number of infections in such metropolitan prefectures and the number of infections nationwide are strongly correlated. However, in other prefectures, the number of infections in that prefecture and the nationwide number are only weakly correlated. Using this property, we can estimate to what extent the change in people’s behavior is due to the number of infections within a prefecture or the number of infections nationwide.

The empirical approach used in this study is as follows. The stay-at-home measure at time t in prefecture i is denoted by y_{it} . The number of new infections at time t in prefecture i is denoted by \tilde{x}_{it} . The number of new infections nationwide is denoted by \tilde{x}_t . The distribution of the number of new infections is skewed to the right because the number of new infections is much larger in a small number of prefectures such as Tokyo than most other prefectures. While many existing studies use

logarithms to cope with such highly skewed distributions, for some of the prefectures in Japan the number of new infections is zero on some days, so that we cannot take logarithms. Following Goolsbee and Syverson (2020), we transformed \tilde{x}_{it} and \tilde{x}_t using the inverse hyperbolic sine. Specifically, we define $x_{it} \equiv \ln(\tilde{x}_{it} + \sqrt{\tilde{x}_{it}^2 + 1})$ and $x_t \equiv \ln(\tilde{x}_t + \sqrt{\tilde{x}_t^2 + 1})$. The estimation equation used in this study is as follows:

$$\begin{aligned}
 y_{it} = & \mu_i + \underbrace{\alpha_0 D_{it}(\text{Emergency declaration}) + \beta_0 D_{it}(\text{School closure})}_{\text{Intervention effect}} \\
 & + \underbrace{\sum_k \alpha_k A_t(E_k) + \sum_k \beta_k A_t(C_k)}_{\text{Information effect}} + \gamma_1 x_{it} + \gamma_2 x_t + \epsilon_{it}
 \end{aligned} \tag{1}$$

where μ_i represents the effect unique to prefecture i . $D_{it}(\text{Emergency declaration})$ is a dummy variable that takes 1 when the state of emergency is active at time t in prefecture i , and 0 otherwise. Similarly, $D_{it}(\text{School closure})$ is a dummy variable that takes 1 when schools are closed at time t in prefecture i , and 0 otherwise. $A_t(E_k)$ represents the government's k th announcement regarding the state of emergency. It is a dummy variable that takes 1 in all prefectures after the k th announcement. Similarly, $A_t(C_k)$ is a dummy variable that represents the government's announcements with regard to school closures.

$\alpha_0 D_{it}(\text{Emergency declaration})$ and $\beta_0 D_{it}(\text{School closure})$ represent the intervention effect. On the other hand, since $\sum \alpha_k A_t(E_k)$ and $\sum \beta_k A_t(C_k)$ represent the effect of announcements with regard to the two policies on the stay-at-home measure, they represent the information effect. Moreover, the response of the stay-at-home measure to the number of new infections in the prefecture and in Japan overall can also be interpreted as representing the information effect.⁶

In Eq. (1), it was assumed that the source of people's information on infections was government policy announcements and the number of new infections. However, people may be able to obtain information about infections by other means. To take this into account, we also conduct estimations

⁶As explained earlier, the values of x_{it} and x_t are obtained by transforming the number of infections using the inverse hyperbolic sine. The coefficients on these two variables, γ_1 and γ_2 indicate that if the number of new infections in a prefecture increases by, for example, 1%, the stay-at-home measure increases by $0.01 \times \gamma_1$ percentage points. For more details on the inverse hyperbolic sine transformation, see Bellemare and Wichman (2020).

using the following equation:

$$y_{it} = \mu_i + \underbrace{\alpha_0 D_{it}(\text{Emergency declaration}) + \beta_0 D_{it}(\text{School closure})}_{\text{Intervention effect}} + \underbrace{\lambda_t + \gamma_1 x_{it}}_{\text{Information effect}} + \epsilon_{it} \quad (2)$$

where λ_t is a time dummy. The specification of the intervention effect is the same as in Eq. (1). On the other hand, regarding the information effect, government policy announcements are expressed as a time fixed effect, since such announcements provide the same information to the residents of all prefectures. For the same reason, the number of new infections nationwide is also expressed as a time fixed effect. However, the time fixed effect differs from Eq. (1) in that it also contains information other than about infections.

Meanwhile, it should be noted that in Eq. (2), it is assumed that except for information on the number of new infections in the prefecture, the residents of all prefectures have the same information about infections, and the impact on their behavior is identical. In practice, however, the information that people have and how they react to information may differ from region to region. For example, the same government announcement may be perceived differently in areas with more infections than in areas with fewer infections. In Section 5, we divide Japan into seven regions and conduct estimations that take into account the possibility that the time fixed effect may differ across regions.

4 Data

4.1 The stay-at-home measure

For our location data, we use the “Mobile Spatial Statistics” provided by DoCoMo Insight Marketing.⁷ The Mobile Spatial Statistics provide location records of about 78 million DoCoMo mobile phones at 10-minute intervals. Specifically, the mobile phone base stations in a particular area know which mobile phones are in the area. Based on this information, and dividing Japan into a mesh of 500m×500m squares, DoCoMo compiles and publishes data on how many mobile phones are in a certain mesh element at a particular time (in 10-minute intervals), together with information on the age and sex of the owners of those mobile phones as well as the area where they live. However, mesh elements with a very small number of phones are excluded to protect individuals’ privacy.

⁷For details, see <https://mobaku.jp/>.

Using this data, we construct our stay-at-home measure in the following two steps. The first step consists of the detection of residential areas. For a certain mesh element, we count the average number of people in the time from midnight to 5am and take this as the nighttime population of that mesh element. Similarly, we count the number of people in the time from 9am to 5pm and take this as the daytime population of that mesh element. An area can then be regarded as a commercial area if the daytime population is greater than the nighttime population and as a residential area if the daytime population is smaller than the nighttime population. Specifically, we define a mesh element as a residential area if it satisfies $\text{daytime population}/\text{nighttime population} < 0.8$ as of January 2020, i.e., before the pandemic. The estimation results presented below were qualitatively the same when we set the threshold to 0.9 or 0.7.

The second step is the calculation of the ratio of those leaving their homes. For mesh elements that in the first step were identified as residential areas, we calculate the number of people leaving home by counting the nighttime population and daytime population on a certain day and subtracting the daytime population from the nighttime population. Next, for each prefecture, we calculate the number of people leaving their homes each day by aggregating the number of people that have left their homes in each mesh element. For example, in Tokyo, as of January (i.e., before COVID), residential areas had a nighttime population of approximately 5.3 million, while the daytime population on weekdays was approximately 3.6 million, so that the number of persons leaving their homes was approximately 1.7 million.

Finally, we take the number of persons leaving their homes in January 2020 (January 6 to 31), i.e., before the outbreak of COVID-19, as the number of persons leaving their homes during normal times, and then calculate for each prefecture and day the percentage difference from the number of people leaving their homes during normal times. We use the deviation rate multiplied by -1 as the stay-at-home measure.⁸

4.2 Number of new infections

The central government and prefectures announce the number of new infections daily. The date of infection is the day when a doctor confirms that a person’s polymerase chain reaction (PCR) test

⁸See Mizuno et al. (2020) for details of the calculation procedure for the stay-at-home measure.

was positive (test result date).⁹ We use figures from the database constructed and published by JAG Japan Co., Ltd.¹⁰ The number of new infections varies greatly depending on the day of the week. In the analysis here, we assume that people make their decision on whether to leave their homes or not based on the trend in new infections over the preceding week, and we therefore use the moving average over the preceding week including the day in question.

4.3 Government's measures against the spread of COVID-19

School closures On February 27, the government requested all elementary schools, junior high schools, high schools, and special needs schools to be closed from March 2 onwards. In response to this, all prefectures except Hokkaido closed schools from March 2.¹¹ We constructed the following two dummy variables for school closures. *School closure* is a dummy variable that takes 1 during the period schools were closed in a particular prefecture, and 0 otherwise. Specifically, except for Hokkaido, the dummy takes 1 from March 2, the day that schools were closed, until the date on which schools were opened again in a particular prefecture. For Hokkaido, the dummy takes a value of 1 from February 27, the day on which schools were closed in that prefecture. The date of the reopening of schools varies widely across prefectures: the earliest date was April 6, while the latest date was June 1. The start and end dates for school closures for each prefecture are shown in Figure 3. Note that if a prefecture closed schools again within a short time of reopening them, we do not regard this as reopening. The second dummy variable, *School Closure Announcement*, represents the announcement of the government's request for schools to close and is set to 1 for all prefectures except Hokkaido from the day after February 27, when the government made the request. For Hokkaido, the dummy is set to 1 from the day following the announcement for Hokkaido on February 26. Meanwhile, the reopening of schools was decided at the prefecture level. Therefore, while the prefectures made announcements, the central government did not, so that we do not use dummies representing the announcement of the end of school closures.

⁹There are two possible ways to define the date of infection: the date a person actually contracted the virus, and the date infection with the virus is confirmed. However, since the infected person may not necessarily know for certain when and where they contracted the virus, the date of infection is often impossible to determine. On the other hand, the date of a test result is clearly recorded. Since the number of infections reported in newspapers and on TV is based on the date of the test result, it is likely that people's decision-making on whether to leave their home is affected by the number of infections based on the date of the test result.

¹⁰See <https://gis.jag-japan.com/covid19jp>. Persons for which the prefecture of residence is unknown or who reside abroad are excluded from the sample.

¹¹For details, see https://www.mext.go.jp/content/20200304-mxt_kouhou02-000004520_1.pdf (in Japanese).

State of emergency The government declared a state of emergency for seven prefectures (Saitama, Chiba, Tokyo, Kanagawa, Osaka, Hyogo, Fukuoka) on April 7, and expanded the state of emergency to all prefectures on April 16.¹² The state of emergency was lifted in 39 prefectures with few infections on May 14, in three more prefectures on May 21, and finally in the remaining five prefectures including Tokyo on May 25. We also construct two types of dummies for the state of emergency. The first, *State of Emergency*, is a dummy that takes 1 when the state of emergency is active in a particular prefecture, and 0 otherwise. For example, for Tokyo, the *State of Emergency* dummy is set to 1 from April 8, the day after a state of emergency was declared for Tokyo, to May 25, when it was lifted. The start and end dates of the state of emergency for each prefecture are shown in Figure 4. The second type of dummies, *State of Emergency Announcement*, represents the government’s announcements regarding the start and end of the state of emergency, and takes 1 for all prefectures from the day after the announcement. Specifically, there were two announcements regarding the start of the state of emergency (April 7 and 16) and three announcements regarding the end of the state of emergency (May 14, May 21, May 25), and we construct five dummy variables, i.e., one for each date.

4.4 Other factors affecting whether people left their homes

To take other factors into account, a rain dummy (*Rain*) and a dummy for weekends and public holidays (*Weekend/Holiday*) are used. The rain dummy takes 1 if the amount of precipitation in the prefectural capital was greater than 0, and takes 0 otherwise. Precipitation data were obtained from the Japan Meteorological Agency website. The *Weekend/Holiday* dummy takes 1 for Saturdays, Sundays, and public holidays, and 0 otherwise.

5 Results

5.1 Baseline Regressions

We used the stay-at-home measure, expressed in percent, as the dependent variable and conducted the estimations using a fixed effects regression model. The results are presented in Table 1. In specification (1), the estimation was performed using the *School Closure* dummy and the *State of Emergency* dummy as explanatory variables, and adding the *Rain* and *Weekend/Holiday* dummies as other explanatory variables. The estimation results indicate that both school closures and the state of emer-

¹²Details of which activities were restricted differed by prefecture. For details, see <https://www3.nhk.or.jp/news/special/coronavirus/tokyo/> (in Japanese).

gency had a significant effect, with the former raising the stay-at-home measure by 11 percentage points and the latter raising it by 16 percentage points.

As highlighted by Coibion et al. (2020) and others, the increase in the number of infections not only triggered government responses, such as the declaration of a state of emergency in Japan's case, it also had the effect of increasing people's fear of infection and led them to voluntarily refrain from leaving their homes. The increase in the stay-at-home measure in specification (1) thus may be due to an increase in the number of infections rather than government measures. Therefore, in specification (2), we added the number of new infections within the prefecture and the number of new infections nationwide as explanatory variables. Adding those variables reduces the coefficients on the *School Closure* and *State of Emergency* dummies from specification (1). However, the coefficients on all dummy variables remain significantly different from zero, indicating that the school closures and the state of emergency still had a statistically significant effect on the stay-at-home measure even after controlling for the number of infections.

Next, in specification (3), in order to control for changes in the stay-at-home measure due to the announcement effect of school closures and the state of emergency, we added a dummy for the announcement of school closures by the government on February 27, while for the state of emergency we added the two dummies for the announcement of the start of the state of emergency and the three dummies for the announcement of the lifting of the state of emergency. For instance, the *State of Emergency Announcement (Start, Apr. 7)* dummy takes 1 for all prefectures from April 8, the day after the announcement, and if the coefficient is positive, this indicates that the state of emergency announcement on April 7 raised the stay-at-home measure regardless of whether the state of emergency applied to a particular prefecture.

Looking at the effects of the closure of schools based on the results for specification (3), the coefficient on the *School Closure* dummy is around 8.3 and significantly different from zero. However, the coefficient on the *School Closure Announcement* dummy is small and not significantly different from zero. This shows that there was a large intervention effect that exceeded the information effect. Next, looking at the effect of the state of emergency declaration, the coefficient on the *State of Emergency* dummy is 8.2, showing that the intervention effect of the state of emergency had more or less the same size as the closure of schools. Moreover, the coefficients on the two dummies for the announcement of the start of the state of emergency are both positive and significant, and the effect

was to increase the stay-at-home measure by 7.4 percentage points in total. On the other hand, the sum of all coefficients for the announcement of the lifting of the state of emergency is close to zero. The above results show that the declaration of the state of emergency had the effect of raising the stay-at-home measure through both the intervention effect and the information effect.

Next, specification (4) includes time fixed effects. Time fixed effects capture factors that have the same effect for all prefectures. They capture the effect that people refrain from leaving their homes in response to various other types of information about the pandemic, not only of government announcements about school closures and the state of emergency. The coefficients on both the *School Closure* dummy and the *State of Emergency* dummy are somewhat smaller than in specification (3) but remain statistically significant.

The blue line in Figure 5 shows the coefficients on the time dummies obtained in this estimation. The time fixed effects show two jumps in April. The first jump corresponds to the declaration of the state of emergency for seven prefectures on April 7, while the second one corresponds to the expansion of the state of emergency to all prefectures on April 16. The dotted red line in Figure 5 shows the predicted values obtained by regressing the time fixed effects estimated in specification (4) on the number of infections nationwide, the declaration of the state of emergency (April 7 and 16), the lifting of the state of emergency (May 14 and May 25), and the *Weekend/Holiday* dummy.¹³ Looking at the results, although the predicted value captures changes in the time fixed effect, and much of the change in the time fixed effect is explained by variables such as the announcements regarding the state of emergency, developments in the predicted value during some periods differ from the actual time fixed effect. For instance, in early February, there is no change in the dotted red line despite the increase in the time fixed effect. The latter likely reflects the fact that the Diamond Princess, a cruise ship with confirmed cases of coronavirus on board called at Yokohama Port on February 3 and was put under quarantine on February 5, which was widely reported in the media and gained public attention. It is possible that this news led people in all prefectures to refrain from leaving their homes.

In specifications (3) and (4), we assumed that residents in all prefectures reacted to government announcements in the same manner. However, people's reaction may differ depending on where they live. Therefore, in specification (5), we divide Japan into seven regions (Tohoku, Kanto, Kinki, Chubu,

¹³Since in specification (3) the coefficients on the *School Closure Announcement* (Feb. 27) and the May 21 announcement of the lifting of the state of emergency were insignificant, they are excluded from the estimation here. We also set the coefficient on the *Weekend/Holiday* dummy to zero.

Chugoku, Shikoku, and Kyushu) and, by specifying the time fixed effect as Day FE \times Region, allow for the possibility that the time fixed effect may differ across regions. Looking at the estimation results, the coefficient on *School Closure* is 4.9, while the coefficient on *State of Emergency* is 7.1, which shows that the coefficient on *School Closure* has dropped significantly. However, the coefficients for both *School Closure* and *State of Emergency* continue to be positive and significant.

Let us compare the results of specification (5) with previous studies on the United States. Goolsbee and Syverson (2020) found that a shelter-in-place (S-I-P) order in a certain county reduced the number of customers visiting retail stores in that county by 7.6%. This is the intervention effect of S-I-P orders in the United States. To compare this with our results, we convert our estimate as follows. As the stay-at-home measure immediately before the state of emergency was declared was 0.17, the level of outings, relative in January 2020 before the outbreak of the pandemic, was 0.83. The coefficient on the *State of Emergency* dummy in specification (5) of 7.1 means that the level of outings dropped to 0.76 due to the intervention effect of the emergency declaration (i.e., $0.83 - 0.07 = 0.76$), and the rate of change in outings is -8.6%. Thus, although the figures are not directly comparable, since Goolsbee and Syverson (2020) measure the reduction in outings using the number of customers visiting stores, the order of magnitude of their result and ours – a decline of 7.6% due to S-I-P orders in the United States and of 8.6% due to the declaration of the state of emergency in Japan – is quite similar. Interestingly, therefore, the intervention by the Japanese government in the form of a “request” and the legally binding lockdowns in the United States had more or less the same intervention effect.

Next, let us compare the coefficient on new infections within the prefecture in specification (5) with results for the United States. The coefficient on the number of new infections within the prefecture is 2.2, and, based on the level of the stay-at-home measure just before the state of emergency was declared, an increase in the number of new infections in the prefecture by 1% led to a reduction in outings of 0.026%.¹⁴ On the other hand, Goolsbee and Syverson (2020) showed that an increase in the cumulative number of deaths from COVID-19 by 1% reduced the number of consumer visits by 0.03%. Although the figures cannot be directly compared, since one refers to the number of infections while the other refers to the number of deaths, they suggest that people in Japan and the United States changed their behavior more or less the same way in response to information on the spread of

¹⁴The level of outings immediately before the state of emergency was declared was 0.83. The coefficient on new infections within the prefecture in specification (5) of 2.2 means that the level of outings dropped by 0.00022 in response to a 1% increase in the number of new infections, implying that the rate of change in outings is -0.026%.

COVID infections.

How should the results of positive and statistically significant coefficients on the *School Closure* and *State of Emergency* dummies be interpreted? Regarding school closures, Prime Minister Abe proposed that schools be closed and requested local governments such as prefectures and municipalities, which have jurisdiction over schools, to do so. Local governments accepted this request, and four days after Prime Minister Abe’s proposal, schools actually closed. This sequence of events suggests that Prime Minister Abe’s request had compelling force on local governments. Presumably, following the decisions by local governments, students (and their parents) started to refrain from leaving their homes. The above-mentioned results that school closures had an intervention effect support this.

Turning to the state of emergency, in contrast with the lockdowns in China, the United States, and Europe, Japan’s state of emergency was not legally binding. There is no rational reason for people to follow “requests and instructions” without penalties such as fines or arrests, and another explanation why the declaration of the state of emergency had the effect it did is needed. One possibility is that the government’s request triggered a change in strategic relationships among companies. For example, a major issue when a firm considers whether to shorten working hours or switch to working from home is how other firms that it does business with react. If business partners do not shorten working hours or allow their employees to work from home, it is not desirable for the firm to switch on its own. And if all firms think like this, no firm will switch. However, if a firm’s business partners switch to shorter working hours or to working from home, it is desirable for the firm to also switch. If this virtuous cycle is created, all firms will shorten their business hours and/or switch to working from home and, as a result, people will refrain from going out. It is possible that the government’s “request” triggered a change in expectations about how other firms will respond, which may have led to coordinated restraint from going out.¹⁵

5.2 Separate estimations for weekdays and weekends/holidays

The estimations in Table 1 took into account that the constant for weekends/holidays and weekdays may differ by including a *Weekend/Holiday* dummy. However, it is possible that not only the constant

¹⁵Another possibility is that the government’s request triggered an increase in social pressure to conform with restraint from going out. This is symbolized, for example, by the emergence of a “self-restraint police” (“virus vigilantes”) that look for and criticize people who are out and about. See the following articles on such virus vigilantes: https://www.washingtonpost.com/world/asia_pacific/in-japan-busy-pachinko-gambling-parlors-defy-virus-vigilantes-and-countrys-light-touch-lockdown/2020/05/14/8ffee74e-9447-11ea-87a3-22d324235636_story.html
<https://www.japantimes.co.jp/news/2020/05/13/national/coronavirus-vigilantes-japan/>.

but also the coefficients on the independent variables may differ between weekends/holidays and weekdays. Whether people leave their homes on weekdays to a large extent depends on how their workplace or school responds to government requests. On the other hand, with regard to going out on weekends/holidays, it is individuals who make the decision, and hence the response depends on how individuals react to requests from the government. By comparing the degree of restraint from going out on weekdays and weekends/holidays, we can further investigate the reasons for the decline in outings.

Columns (1) and (2) in Table 2 show the estimation results using weekday observations only, while columns (3) and (4) show those using weekend/holiday observations only. Columns (1) and (3) correspond to specification (1) in Table 1, while columns (2) and (4) correspond to specification (5) in Table 1. Comparing the results in columns (1) and (3) shows, firstly, that the *School Closure* dummy is positive and significant not only for weekdays but also for weekends/holidays. Refraining from going out on weekends should be interpreted as voluntary, since school closures did not order people to refrain from going out on weekends/holidays. Second, the coefficients on the *School Closure* and *State of Emergency* dummies are both larger for weekends. Eichenbaum et al. (2020) point out that the pandemic affects the behavior of both workers and consumers. That is, workers hesitate to come into contact with others at the workplace and hesitate to go to the workplace, while consumers refrain from consuming because they worry about contact with others at the place of consumption. The estimation results here thus can be interpreted as suggesting that restraint from going out on weekends/holidays was larger because the change in behavior of consumers was greater than that of workers.

Like specification (1) in Table 1, on which they are based, specifications (1) and (3) in Table 2 do not distinguish between the intervention effect and the information effect, so that the coefficients on the *School Closure* and *State of Emergency* dummies contain both effects. On the other hand, specifications (2) and (4), in order to control for other factors affecting the stay-at-home measure, also contain the number of new infections in the prefecture and time dummies. The time fixed effects are specified such that they may differ across the seven regions.

Looking at the estimation results for specifications (2) and (4) in Table 2, we find, firstly, that the coefficients on the *School Closure* and *State of Emergency* dummies are larger for weekdays. It is not surprising that the intervention effect of school closures is greater on weekdays. On the other

hand, with regard to the *State of Emergency* dummy, the greater intervention effect for weekdays suggests that workers responded more actively than consumers to the government’s requests. This can be interpreted as resulting from firms actively promoting the shortening of business hours and the shift to work from home in response to the government’s requests. Second, compared with specifications (1) and (3), the relative sizes of the *School Closure* and *State of Emergency* dummies for weekdays and weekends/holidays are reversed. This suggests that the information effect, in contrast with the intervention effect, is larger for weekends/holidays than weekdays. This can be interpreted as indicating that the information effect is driven by consumers, not by firms or workers.

5.3 Weighted least squares regression

The stay-at-home measure is created from smartphone data for each prefecture; however, since the number of smartphones differs across prefectures, the accuracy of the stay-at-home measure also differs across prefectures. To take this into account, in Table 3, we used weighted least-squares estimation, using the number of smartphones in the residential areas of each prefecture as weights.

Looking at the estimation results, the coefficients on the *School Closure* and *State of Emergency* dummies are very similar to those in Table 1. Specifically, the state of emergency had the effect of reducing outings by 20 percentage points compared to before the pandemic. Of these 20 percentage points, 7 percentage points were due to the intervention effect, while the remainder was due to the information effect. On the other hand, school closures had the effect of reducing outings by 12 percentage points compared to before the pandemic. Of these 12 percentage points, 5 percentage points were due to the intervention effect. Turning to the coefficients on the number of new infections, these are somewhat larger than in Table 1. A 1% increase in the number of new infections in a prefecture reduced outings in that prefecture by 0.022 percentage points.

Next, Figure 6 presents a decomposition of changes in the stay-at-home measure for Tokyo using the estimation results from specification (5) in Table 3. During the period examined here, the stay-at-home measure for Tokyo peaked at 55% on May 1, and dividing the increase from January into the contribution of the various components shows that the intervention effect of school closures contributed 5 percentage points and the intervention effect of the state of emergency contributed 7 percentage points, for a combined intervention effect of 12 percentage points. On the other hand, the contribution of the number of new infections within Tokyo prefecture was 12 percentage points, while

the contribution of the time fixed effect was 30 percentage points, for a combined information effect of 42 percentage points. Thus, the intervention effect contributed about a quarter and the information effect about three quarters to the reduction in outings, indicating that the dominant channel for changes in behavior was the information effect.

6 Summary and Policy Implications

Recent theoretical research on COVID-19 suggests that people have an incentive to refrain from going out to reduce their risk of becoming infected. However, once individuals are infected and are asymptomatic or have only minor symptoms, they have little incentive to avoid infecting others and hence to refrain from going out, so that they unwittingly may infect others. Given this externality, the health damage to society as a whole is magnified and can lead to socially undesirable consequences (see, for example, Eichenbaum et al., 2020). An important implication of this theoretical prediction is the need for government intervention. In other words, from the perspective of preventing the spread of infections, it is justified that the government deprives people of the freedom to leave their homes.

In China, the United States, and Europe, legally binding interventions such as lockdowns have been used to prevent people from leaving their homes. On the other hand, in Japan, such intervention took the form of a government “request” calling on people to refrain from going out. At the time, there were many in Japan who were concerned that such a “request” would not have a sufficient effect. However, the analysis in this study has shown that the Japanese government’s declaration of a state of emergency to a certain extent was successful in changing people’s behavior. Specifically, in prefectures where a state of emergency was declared, outings (Number of persons going out \times Time spent out) fell by 8.6%. According to Goolsbee and Syverson (2020), in the United States, the number of customers visiting retail stores decreased by 7.6% in counties that had imposed a lockdown. Thus, interestingly, the effects of government intervention were similar in Japan and the United States.

What does this finding mean? First, both the compulsory lockdown in the United States and the voluntary lockdown in Japan had a substantial impact on people’s mobility. In both countries, the movement of people decreased substantially compared to normal times. However, the lockdowns were responsible only for part for this reduction. The remainder of the reduction was due to the fact that these measures increased people’s awareness of the seriousness of the pandemic, for example through government announcements and the release of the number of infections and deaths; in other words, the

remainder was due to the information accompanying these measures, which led people to voluntarily refrain from going out. Thus, the lesson of the experience both in Japan and the United States is that in order to contain infections, it is necessary to provide people with correct information in a timely manner and to encourage voluntary changes in behavior.

Second, if government intervention is needed, what is preferable: a compulsory lockdown or voluntary lockdown? The advantage of a compulsory lockdown is that its effects can be predicted to some extent, and uniform changes in behavior can be expected for a wide range of people (though not all). On the other hand, from citizens' point of view, a compulsory lockdown imposes severe restrictions on their personal freedom: to avoid being penalized with a fine or arrest, people have to respond in a uniform manner regardless of their individual circumstances. By contrast, in a voluntary lockdown, there is room for each citizen to decide whether or not to comply with the request, based on their own personal circumstances. On the other hand, though, the effect is uncertain. Whether a similar request for voluntary lockdown would be effective in Japan in the future or in other countries such as the United States or in Europe is unclear. While this study suggests that the government's request may have provided the impetus for cooperation to avoid the spread of COVID-19 infections, further analysis is needed.

Notes: Figures in parentheses are cluster-robust standard errors. *, **, and *** denote statistical significance at the 10%, 5% and 1% level, respectively. For the number of new infections within prefectures and nationwide, the inverse hyperbolic sine transforms ($\operatorname{arcsinh}(x) = \ln(x + \sqrt{x^2 + 1})$) were used.

Table 2: Estimation Distinguishing between Weekdays and Weekends/Holidays

	(1)	(2)	(3)	(4)
School Closure	10.040*** (0.293)	5.558*** (0.936)	13.553*** (0.557)	3.302*** (0.700)
State of Emergency	13.621*** (0.869)	7.085*** (0.970)	18.616*** (0.580)	6.887*** (0.768)
No. of New Infections Within Prefecture		2.178*** (0.369)		2.290*** (0.318)
Rain	0.863*** (0.295)	0.722*** (0.193)	3.186*** (0.475)	1.039*** (0.277)
Obs.	5499	5499	2726	2726
Adjusted R^2	0.682	0.951	0.679	0.973
Sample	Weekdays	Weekdays	Weekends and Holidays	Weekends and Holidays
FEs	Prefecture	Prefecture Day \times Region	Prefecture	Prefecture Day \times Region

Notes: Figures in parentheses are cluster-robust standard errors. *, **, and *** denote statistical significance at the 10%, 5% and 1% level, respectively. For the number of new infections within prefectures, the inverse hyperbolic sine transforms ($\operatorname{arcsinh}(x) = \ln(x + \sqrt{x^2 + 1})$) were used.

Table 3: Weighted Least Squares Regressions

	(1)	(2)	(3)	(4)	(5)
School Closure (SC)	12.119*** (0.269)	3.413*** (0.529)	9.325*** (0.523)	8.398*** (1.169)	4.797*** (1.002)
State of Emergency (SE)	20.181*** (1.471)	14.970*** (0.701)	8.339*** (0.700)	8.155*** (0.743)	7.045*** (0.983)
SC Announcement (Feb. 27)			0.141 (0.527)		
SE Announcement (Start, Apr. 7)			4.413*** (0.774)		
SE Announcement (Start, Apr. 16)			6.482*** (0.466)		
SE Announcement (End, May 14)			3.489*** (0.887)		
SE Announcement (End, May 21)			0.146 (0.518)		
SE Announcement (End, May 25)			-2.943*** (0.896)		
No. of New Infections Within Prefecture		1.808* (0.919)	2.960*** (0.604)	3.255*** (0.558)	2.234*** (0.361)
No. of New Infections Nationwide		2.644*** (0.245)	0.468** (0.216)		
Rain	3.408*** (0.561)	2.944*** (0.309)	2.638*** (0.238)	2.307*** (0.375)	0.873*** (0.235)
Weekend/Holiday	6.143*** (0.378)	6.175*** (0.369)	6.292*** (0.360)		
Obs.	8225	8225	8225	8225	8225
Adjusted R^2	0.708	0.819	0.886	0.942	0.977
FEs	Prefecture	Prefecture	Prefecture	Prefecture Day	Prefecture Day×Region
Weights	No. of smartphone users in each prefecture as of Jan 2020				

Notes: Figures in parentheses are cluster-robust standard errors. *, **, and *** denote statistical significance at the 10%, 5% and 1% level, respectively. For the number of new infections within prefectures and nationwide, the inverse hyperbolic sine transforms ($\operatorname{arcsinh}(x) = \ln(x + \sqrt{x^2 + 1})$) were used.
